

Timing of the Penrose R-Process

Richard Mould*

Abstract

The Penrose reduction theory is applied to a particle/detector interaction where the time that it takes for a particle capture (and reduction of the original state) is constrained by the requirement that $\Delta t = \hbar/\Delta E$. The usual interpretation of this equation is found to conflict with the Hamiltonian dynamics of the interaction. Another interpretation of this equation seems to solve that problem, but then another difficulty arises. We conclude that the Penrose theory cannot reflect the timing implicit in the Hamiltonian dynamics unless it can be amended to take account of the probability current flow between competing states.

Introduction

Penrose assumes that Nature will not tolerate significant differences in geometry between two competing eigenstates in a quantum mechanical system. If the metrical uncertainty between the states is greater than the Planck length, then according to Penrose, there will be an “objective” collapse (**R**-process) of the wave function that selects one component of the superposition and drives the other to zero [1]. This collapse is coupled to the onset of environmental decoherence between the components, rendering them locally incoherent.

The timing of a collapse is said to depend on the difference between the gravitational energy ΔE of the competing eigenstates including their environments. The time Δt allowed for the **R**-process to occur is then given by $\hbar/\Delta E$. In the macroscopic case to be considered, the difference in gravitational energy of the competing environments will dominate the effect, guaranteeing a virtually instantaneous decay of the state function as classically expected (ref. 1, pp. 341-342).

The Interaction

In another paper [2], the author considers an interaction in which a particle/detector system is given by $\Phi(t) = \exp(-iHt)\psi_i D_i$, where ψ_i and D_i are the initial states of the incoming particle and the detector, and H is the Hamiltonian divided by $\hbar$. Because H includes an interaction term between ψ and D , the resulting state $\Phi(t)$ is an entanglement in which the particle variables and the detector variables are not separable. However, $\Phi(t)$ is a superposition (in the representation considered) so we can group its components in any way that we like. I form two major components: (1) those detector states D_0 in which there is no particle capture, and (2) those detector states $D_1(t)$ in which there is a particle capture. Let $\psi(t)$ represent the free particle as a function of time, including all the incoming and scattering components. It is therefore entangled with D_0 . But since the detector is macroscopic, we may approximate D_0 to be a constant that can be factored out of $\psi(t)$. The captured particle is included in the component $D_1(t)$. This gives

$$\Phi(t \geq t_0) = \psi(t)D_0 + D_1(t) \quad (1)$$

where $D_1(t)$ is equal to zero at t_0 and increases in time, whereas $\psi(t)D_0$ is normalized to one at t_0 and decreases in time.

When the environments E_0 and E_1 are attached to these components the ΔE associated with these macroscopic components is very large; so, the Penrose theory predicts an “immediate” stochastic reduction. But that cannot be correct, for the Hamiltonian has other plans.

The Hamiltonian requires that the superposition in eq. 1 will last as long as is necessary for the interaction to run its course. The timing of a collapse (i.e., a particle capture) is determined by the probability current flowing from the first to the second component, and that is determined by the rate at which the particle wave approaches and overlaps the detector at each moment. For low-level radioactive emissions yielding particle waves that are spread widely over space, the interaction in eq. 1 might last for hours or days. In that case the superposition will last for hours or days. So the ‘time’ of a particle capture in this treatment is not a function of decoherence or gravitational thresholds. It is, *and should be*, a function of the parameters of the incoming particle and the cross section of the particle with the detector. The dynamics of the Hamiltonian therefore conflict with the predictions of the Penrose theory.

Alternative Interpretation

There is another difficulty with the above interpretation of $\hbar/\Delta E$. It is said that a reduction occurs immediately because of the great difference in gravitational energy between the first and second components in eq. 1. But “immediately” means at time t_0 , and at time t_0 the second component is equal to zero. How can the second component be gravitationally competitive with the first component if it is equal to zero?

Normally the decay time of a quantum mechanical system is given by $\hbar/\Delta E$, where ΔE is its Heisenberg spread in energy. In the above example ΔE would then correspond to the spread in the energy of the incoming particle wave packet, and the time $\hbar/\Delta E$ would correspond to the time that it takes for the packet to pass over the detector. This ‘alternative’ interpretation of ΔE would give the right result. The trouble is, the expression $\Delta t = \hbar/\Delta E$ is a minimum condition, so Δt might be much larger than $\hbar/\Delta E$.

Imagine that the incoming particle is a photon that is divided into two equal pulses by a half-silvered mirror. Let both pulses be directed toward the detector, which is represented in the accompanying figure by a shaded rectangle; and assume that the total cross section is such that there is a probability of 1.0 that the particle will be captured. Then the uncertainty of the time of interaction is given by Δt which is approximated in the figure as the time interval between the pulses. This interval can be made indefinitely large, so the interaction time can be made indefinitely large without changing the uncertainty in energy ΔE .

If the particle is not captured when the first pulse goes by, it will be captured when the second pulse arrives at the detector. Since the theory prescribes that a reduction must occur within a time $\hbar/\Delta E < \Delta t$, a reduction will necessarily occur *between* the two pulses according to our second (alternative) interpretation of $\hbar/\Delta E$. This is certainly not correct. Another way of putting this is to say that the second component in eq. 1 would be stochastically chosen at a time when there is no probability current flowing into it – also not correct. So the second interpretation of $\hbar/\Delta E$ is just as problematic as the first. This argument disqualifies any interpretation of $\hbar/\Delta E$ because Δt in the figure can be made indefinitely large.

The Penrose theory attributes state reduction (**R**-process) to a gravitational tension that exists between competing components in a quantum mechanical superposition. However, the theory does not work as a function of time because it cannot generally replicate Hamiltonian dynamics. If the theory is to be modified in such a way that it does follow the Hamiltonian, it must find a way to introduce *probability current* as a determining influence. The importance of probability current to *any* theory of state reduction is explained in ref. 2. A Penrose-like gravitational tension must have something to do with the dynamics between states, and not just their respective static magnitudes.
